Heterotopic Ossification (HO) is a well known sequela of trauma, burns, head injury, and certain congenital or acquired metabolic conditions which has a predilection for the hip and elbow. This disease has uncommonly been reported after elective open shoulder surgery and in particular, reports have been extremely rare after minimally invasive surgery. To our knowledge there have been no reports of heterotopic ossification following arthroscopic rotator cuff (RC) repair in peer reviewed literature. The clinical importance of heterotopic bone after shoulder surgery remains uncertain due to inconsistent definitions, varying correlation of severity of symptoms with radiographic findings, and lack of data on efficacy of treatment. We present a case of severely symptomatic heterotopic bone formation after arthroscopic RC repair which was successfully treated with excision of the heterotopic bone, interval release, and manipulation.
